To the Editor,

Neurological disorders are among the leading causes of disability and mortality worldwide, yet clinical neurology continues to focus predominantly on diagnosing and treating disease after symptoms become apparent. While remarkable progress has been made in neuroimaging, molecular diagnostics, and disease-modifying therapies, many neurological conditions are still identified only after irreversible neuronal damage has occurred. This reactive approach limits therapeutic success and places an increasing burden on patients, caregivers, and healthcare systems. It is time to reconsider whether the future of neurology should place greater emphasis on prevention rather than intervention alone.

Many common neurological disorders, including Alzheimer's disease, Parkinson's disease, stroke, and multiple sclerosis, develop gradually over several years before clinical manifestations become evident. During this preclinical phase, pathological processes such as protein aggregation, chronic neuroinflammation, vascular dysfunction, oxidative stress, and neuronal degeneration are already underway. By the time memory impairment, movement disorders, or neurological deficits become clinically recognizable, opportunities for preventing disease progression may have already diminished. This observation suggests that neurological care should evolve from a symptom-driven model toward one that identifies risk and intervenes earlier.

Recent advances in biomedical science provide encouraging opportunities for this transformation. Blood-based biomarkers, advanced neuroimaging techniques, genetic testing, and digital health technologies are improving our ability to detect early biological changes associated with neurological diseases. At the same time, wearable devices and remote monitoring systems are enabling continuous assessment of sleep, gait, balance, cognitive performance, and physical activity. These innovations may help clinicians recognize subtle functional changes before conventional neurological examination identifies clinically significant abnormalities.

Artificial intelligence (AI) has further expanded the possibilities for predictive neurology. Machine learning algorithms can analyze complex clinical, imaging, and molecular datasets to identify patterns associated with disease risk and progression. Rather than replacing neurologists, these technologies should serve as decision-support tools that enhance clinical judgment and improve diagnostic accuracy. Their greatest value may lie in identifying individuals who would benefit from preventive interventions long before permanent neurological injury develops.

Equally important is the recognition that many neurological disorders are influenced by modifiable lifestyle and vascular risk factors. Hypertension, diabetes mellitus, obesity, smoking, physical inactivity, poor sleep quality, hearing impairment, depression, and social isolation have all been associated with increased risk of cognitive decline, stroke, and dementia. Addressing these factors through patient education, lifestyle modification, and routine preventive healthcare could substantially reduce the future burden of neurological disease. Unfortunately, preventive counseling remains underutilized in many neurological settings, where clinical attention is understandably focused on managing established disease.

Preventive neurology should therefore become a routine component of neurological practice rather than an optional

CC BY

consideration. Risk assessment, patient education, cognitive health promotion, and long-term monitoring should be integrated into standard neurological care. Collaboration between neurologists, primary care physicians, cardiologists, endocrinologists, rehabilitation specialists, psychologists, and public health professionals will be essential to developing comprehensive prevention strategies. Such interdisciplinary approaches may improve patient outcomes while simultaneously reducing healthcare costs associated with advanced neurological disability.

Despite these promising developments, important challenges remain. Predictive biomarkers require further validation across diverse populations before widespread clinical implementation. Many emerging technologies remain expensive and inaccessible, particularly in low- and middle-income countries. Ethical considerations regarding genetic risk prediction, privacy, informed consent, and equitable access to advanced diagnostics must also be carefully addressed. Furthermore, clinicians require appropriate education and training to interpret complex molecular and digital health information responsibly.

Nevertheless, these challenges should not discourage progress. Instead, they emphasize the importance of carefully designed clinical research, evidence-based implementation strategies, and international collaboration. As our understanding of neurological disease continues to evolve, healthcare systems should gradually transition from responding to neurological damage toward preserving neurological health throughout the lifespan.

Conclusion

Preventing neurological disorders before symptoms appear should become a central objective of modern neurology. Advances in biomarkers, artificial intelligence, digital health technologies, and preventive medicine provide an unprecedented opportunity to detect disease earlier and intervene before irreversible neuronal injury occurs. Although scientific, ethical, and healthcare-system challenges remain, integrating predictive and preventive strategies into routine neurological practice may improve patient outcomes, reduce the global burden of neurological disorders, and redefine the future of brain healthcare.
