To the Editor,

Radio astronomy has continuously expanded humanity's understanding of the Universe by revealing phenomena hidden from optical observations. However, the rapidly increasing presence of terrestrial radio-frequency interference (RFI), expanding satellite communication systems, and ionospheric limitations have created significant challenges, particularly for low-frequency radio observations. In this context, the lunar far side represents an extraordinary opportunity to establish a new generation of radio astronomy facilities beyond Earth's technological noise environment.

The Moon's far side provides a naturally protected radio-quiet zone because the lunar body blocks direct radio emissions from Earth and many artificial sources. This unique characteristic makes it an ideal location for exploring frequency ranges below approximately 50 MHz, which remain largely inaccessible from terrestrial observatories. Observations at these wavelengths could address some of the most fundamental questions in modern astrophysics, including the origin of the first stars, early galaxy formation, cosmic reionization, and the properties of dark matter.

One of the most important scientific motivations for lunar far-side radio astronomy is the detection of the redshifted 21-cm hydrogen signal from the Cosmic Dark Ages. This unexplored period between recombination and the formation of the first luminous structures contains critical information about the evolution of the early Universe. Measurements of this signal could provide direct evidence about the emergence of the first stars and galaxies and may reveal new physics beyond current cosmological models. However, Earth-based observations of this signal are severely limited by ionospheric disturbances and overwhelming human-generated radio interference.

Recent advances in lunar exploration have demonstrated that radio astronomy from the Moon is becoming technically achievable. The Chang'e-4 mission successfully achieved the first landing on the lunar far side and carried the Low-Frequency Radio Spectrometer (LFRS), providing valuable information about the lunar radio environment and validating the operation of radio instruments under lunar conditions. These achievements represent an important milestone toward future permanent astronomical facilities on the lunar surface.

Several innovative concepts are now being developed to utilize the lunar far side as a scientific platform. The Lunar Crater Radio Telescope (LCRT) proposes placing a large wire-mesh radio telescope inside a natural lunar crater, using the crater walls as protection against electromagnetic interference and environmental hazards. Such a design could enable ultra-long-wavelength observations that are impossible from Earth. Similarly, the Far View concept proposes a large-scale lunar radio array consisting of thousands of antennas manufactured using lunar resources, potentially creating a massive interferometric facility dedicated to Cosmic Dark Ages studies.

The development of lunar radio astronomy also introduces significant technological challenges. Autonomous robotic deployment, long-duration operation, lunar dust mitigation, power management, communication infrastructure, and advanced data-processing systems must be addressed before large-scale observatories can be constructed. Artificial intelligence and autonomous scientific operations will likely become essential components of future lunar observatories, allowing efficient calibration, signal processing, and scientific decision-making with minimal

CC BY

human intervention.

Beyond cosmology, lunar radio observatories could provide important contributions to planetary science and astrophysics. Low-frequency radio observations could improve our understanding of planetary magnetic fields, solar activity, cosmic magnetic structures, and possible radio emissions from exoplanets. The radio-quiet lunar environment may also provide a valuable location for future searches for extraterrestrial technological signals.

The next decade is likely to represent a transition from conceptual studies toward practical lunar astronomical infrastructure. International cooperation among space agencies, research institutions, and private aerospace organizations will be essential for achieving this ambitious goal. Similar to how terrestrial observatories such as large radio interferometers transformed astronomy in the twentieth century, lunar radio facilities may define the next era of observational discovery.

In conclusion, the lunar far side should no longer be considered merely a destination for exploration but rather a scientific platform capable of addressing some of the most profound questions in astrophysics. Establishing radio observatories on the Moon would provide humanity with access to an unexplored electromagnetic window and could fundamentally transform our understanding of the Universe.
