Abstract

Background: Most of the shoulder pathologies can be treated by shoulder arthroscopy. The major problem for the surgeon who has just started the shoulder arthroscopy is the difficulty of finding the joint in the first attempt. This results with uncontrolled fluid leakage to the surrounding soft tissues. Especially in obese patients this condition prolongs the operation duration. To prevent this, the following procedure is recommended.

Methods: The technique can be summarized as follows: i. after entering from the posterior portal; the arthroscope is placed on to the three way canula, however the joint is not filled with fluid. ii. An injector is used to inject air from the canula. iii. Pumping the air makes the joint more visible and after dry diagnostic arthroscopy the fluid can be pumped.

Results: This technique enables the surgeon to fill the joint after being sure that the canula is in the joint to prevent uncontrolled fluid extravasation. By this procedure the natural view of the joint can also be seen. A diagnostic arthroscopy can easily been done.

Discussion and conclusion: We recommend this technique in the first 10 shoulder arthroscopy of the new starter surgeon. It is suggested to apply classical procedures after gaining considerable experience. But the technique can be used for dry diagnostic shoulder arthroscopy also by an experienced surgeon.

Introduction

Arthroscopy of the shoulder is a well established and routine procedure. Most of the shoulder pathologies can be treated by shoulder arthroscopy. It has become a popular therapeutic and diagnostic procedure during the past two decades. The major problem for the surgeon who has just started the shoulder arthroscopy is the difficulty of finding the joint in the first attempt. This results with uncontrolled fluid leakage to the surrounding soft tissues. Especially in obese patients this condition prolongs the operation duration [1].

In other fields of surgery, such as laparoscopy, water is not used to maintain the optic cavity; instead carbon dioxide is used. Levin et al devised a balloon for this purpose when dissecting in soft-tissue planes [2]. Other researchers have used traction from the soft tissues to develop the optic cavity when raising flaps [3,4]. To summarize, water is neither crucial nor necessary to see inside any given cavity.

This article presents our experience with more than 200 cases in the technique of dry arthroscopy of the shoulder which is still being used by some shoulder surgeons.

Surgical Technique

All surgical procedures are performed with the patient in the seated beach-chair position under general anesthesia. Routine portals are used. Steps can be summarized as follows: After entering from the posterior portal; the arthroscope is placed on to the three way canula however the joint is not filled with fluid. An injector is used to inject air from the three way canula. After pumping the air manually with a 50 cc injector, the joint becomes more visible (Figure 1). The remaining steps of the joint exploration do not vary from the wet technique. This method enables the surgeon to fill the joint after being sure that the canula is in the joint. By this procedure the natural view of the joint and the pathology can easily be seen without a fluid effect of blurring with some bleeding (Figure 2).

Our recommendation is to avoid too close to the scope tip when examining the tissues to avoid splashes. If there is a minor splash onto the scope’s tip it can be removed by gently rubbing the tip on the local soft tissue. This will clear the view sufficiently.
Discussion

Traditionally, shoulder arthroscopy has been performed with water in an attempt to maintain the optic cavity; however, as shown in other areas of the body (abdomen, thorax) or when raising flaps, water is not required [2-4]. Water has inherent disadvantages. It runs out through portals, causing loss of vision, and may cause some complications.

Fluid extravasation has been reported associated with uncontrolled pressure of the joint. Excessive extravasation to avoid neurologic injury and respiratory problems requiring aggressive airway management is also reported [1,5-7]. Repeated entering to the shoulder may cause different portals that leads to fluid extravasation. The dry technique is an easy method for new starters to shoulder arthroscopy in being sure that the canula is in the joint cavity. On the other hand the technique enables the surgeon to see the natural view of the tissues in the joint which is a preferred method for some surgeons [8]. For example it is difficult to see a hyperemic area under pumps pressure. Sometimes fluid makes it difficult to see inside because of the blurring due to the bleeding in the cavity. This is usually not a problem for the experienced surgeon. But a new starter needs time to see and overcome this blurring with more fluid leakage to the tissues.

Although we do not have any experience, the dry technique is probably inappropriate when using thermal or laser probes. The generated heat cannot dissipate by air alone and, in our opinion, there is a risk of widespread, uncontrollable soft tissue and/or chondrocyte burning. For this reason we do not advise using this type of device without water running through the area. Also, some signs and findings differ from those found in the wet technique. For example the inflamed synovium will not float, it will stick to the capsule: its redness and hypertropy will point to the existence of synovitis.

Conclusion

We recommend this technique in the first 10 shoulder arthroscopy of the new starter surgeon. But an experienced surgeon can still use the technique to see the natural structure of the joint such as hyperemic areas in the joint.
